REVIEW PAPER

Abstract — A reference facility for the calibration and intercomparison of active and passive detectors in broad neutron fields has been available at CERN since 1992. A positively charged hadron beam (a mixture of protons and pions) with momentum of 120 GeV/c hits a copper target, 50 cm thick and 7 cm in diameter. The secondary particles produced in the interaction traverse a shield, at 90° with respect to the direction of the incoming beam, made of either 80 to 160 cm of concrete or 40 cm of iron. Behind the iron shield, the resulting neutron spectrum has a maximum at about 1 MeV, with an additional high-energy component. Behind the 80 cm concrete shield, the neutron spectrum has a second pronounced maximum at about 70 MeV and resembles the high-energy component of the radiation field created by cosmic rays at commercial flight altitudes. This paper describes the facility, reports on the latest neutron spectral measurements, gives an overview of the most important experiments performed by the various collaborating institutions over recent years and briefly addresses the possible application of the facility to measurements related to the space programme.

INTRODUCTION

In its 1990 recommendations the International Commission on Radiological Protection (ICRP) stated that exposure of civil aircrew has to be considered as being occupational⁽¹⁾. This has been translated into a legal requirement in the European Union in 1996 by the Council Directive 96/29⁽²⁾. The ICRP recommendations have boosted several research activities worldwide aiming at determining dose equivalent rates for the various commercial routes as well as establishing experimental and computational tools for dosimetry of aircrews. In this framework the European Union has sponsored since 1992 coordinated actions with the aim to merge the expertise of several research institutions in the field of cosmic ray physics and dosimetry^(3–6). A wide range of active instruments and passive devices has been employed in several measurement campaigns, mainly on board commercial flights but also on some dedicated flights (see, for example, References 3, 4, 7–13).

If both the energy and angular response characteristics of a device and the energy and direction distribution of the radiation field to be determined are well known (either experimentally or theoretically), the response data can be folded with the field data to obtain a response correction factor. In practice these conditions are rarely met for in-flight measurements. An alternative approach is thus to determine the response of the device either in the radiation field of interest (a ‘field calibration’) or in an experimental radiation field of suf-

ficiently similar characteristics (a ‘simulated workplace field’) (Figure 1).

The direct field calibration in aircraft requires a reference instrument in principle capable of determining the true value of ambient dose equivalent for all radiation components and energies. In this respect the tissue-equivalent proportional counter (TEPC) is presently considered the instrument best suited for field calibration in the cosmic radiation field at flight altitudes⁽¹⁴⁾. However, the availability of a reference radiation facility providing particle composition and spectral fluences similar to those in the cosmic radiation field at commercial flight altitudes (10–20 km) is of obvious interest. The EU funded programmes placed significant emphasis on calibration and characterisation of detectors. An important element in these programmes is the simulation of the cosmic ray field at aircraft altitudes at an experimental facility available at CERN, which provides a reference base for both passive and active instruments⁽¹⁵⁾.

The facility is a development of an idea conceived by Stevenson in 1987, when an experimental area was set up to study the spatial distribution of hadron and low-energy neutron fluence and of absorbed dose in the cascades induced in iron and lead calorimeter structures irradiated by high-energy hadron beams^(16–19). The CERN–EU reference radiation facility was set up in 1992 and subsequently upgraded to its present form in 1993. Minor modifications (addition of some extra shielding just upstream of the dump and of an access maze), which did not affect the particle spectra at the reference exposure locations, were made in 1997. In addition to the interest for testing active instrumentation

and passive detectors used around high-energy particle accelerators, this reference field is considered to be sufficiently similar to the cosmic ray field encountered at 10–20 km altitude such that instrumentation can be tested, inter-compared and calibrated at CERN and subsequently used for in-flight measurements on aircraft. The facility actually provides a mixed field of neutrons, photons, muons, electrons, protons and pions — and it is widely used to test both low- and high-LET sensitive devices — but the main component is represented by the neutron field. Although there are several laboratories offering monoenergetic reference neutron fields, such as PTB in Braunschweig, Germany, PSI in Villigen, Switzerland and UCL in Louvain-la-Neuve, Belgium, the CERN field is unique in providing a broad neutron spectrum specifically adapted to the above purpose.

The aim of the present paper is to describe the facility, which has previously been illustrated only in two conference proceedings^(20,21), to report on the latest neutron spectral measurements, to give an overview of the most important experimental investigations carried out by the various collaborating institutions over recent years, and to address briefly its possible application to measurements related to the space programme.

THE CERN-EU HIGH-ENERGY REFERENCE FIELD (CERF) FACILITY

The CERN-EU high-energy Reference Field (CERF) facility is installed in one of the secondary beam lines (H6) from the Super Proton Synchrotron (SPS), in the North Experimental Area on the Prévessin (French) site

of CERN (Figures 2 and 3). A positive hadron beam with momentum of usually 120 GeV/c is stopped in a copper target, 7 cm in diameter and 50 cm in length, which can be installed in two different positions inside an irradiation cave. In the past 205 GeV/c positive and negative hadron beams (respectively a mixture of about 2/3 protons and 1/3 positive pions or negative pions only) were also used. The secondary particles produced in the target traverse a shielding, on top of these two positions, made up of either 80 cm concrete or 40 cm iron. These roof shields produce almost uniform radiation fields over two areas of $2 \times 2 \text{ m}^2$ located at approximately 90° with respect to the incoming beam direction, each of them divided into 16 squares of $50 \times 50 \text{ cm}^2$. Each element of these ‘grids’ represents a

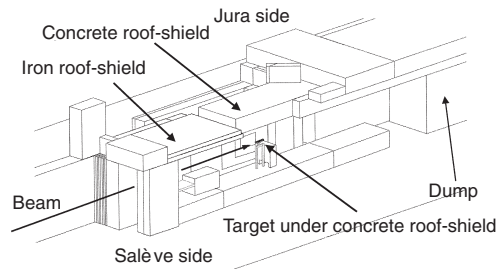

Figure 2. Axonometric view of the CERF facility in the North Experimental Hall on the Prévessin site of CERN as modelled in FLUKA. The side shielding on the Salève side is removed to show the inside of the irradiation cave with the copper target set-up.

THE CERN-EU REFERENCE FIELD (CERF) FACILITY

reference exposure location. Additional measurement positions are available behind the lateral shielding of the irradiation cave, at the same angles with respect to the target as for the two roof positions. Shielding is either 80 cm or 160 cm concrete, and at both positions 8 additional exposure locations (arranged in 2×4 grids

made up of the same 50×50 cm² elements) are provided. The nominal measurement locations (the reference field) are at the centre of each square at 25 cm height above floor, i.e. at the centre of a $50 \times 50 \times 50$ cm³ air volume, where the radiation field is calculated. The intensity of the primary beam is monitored

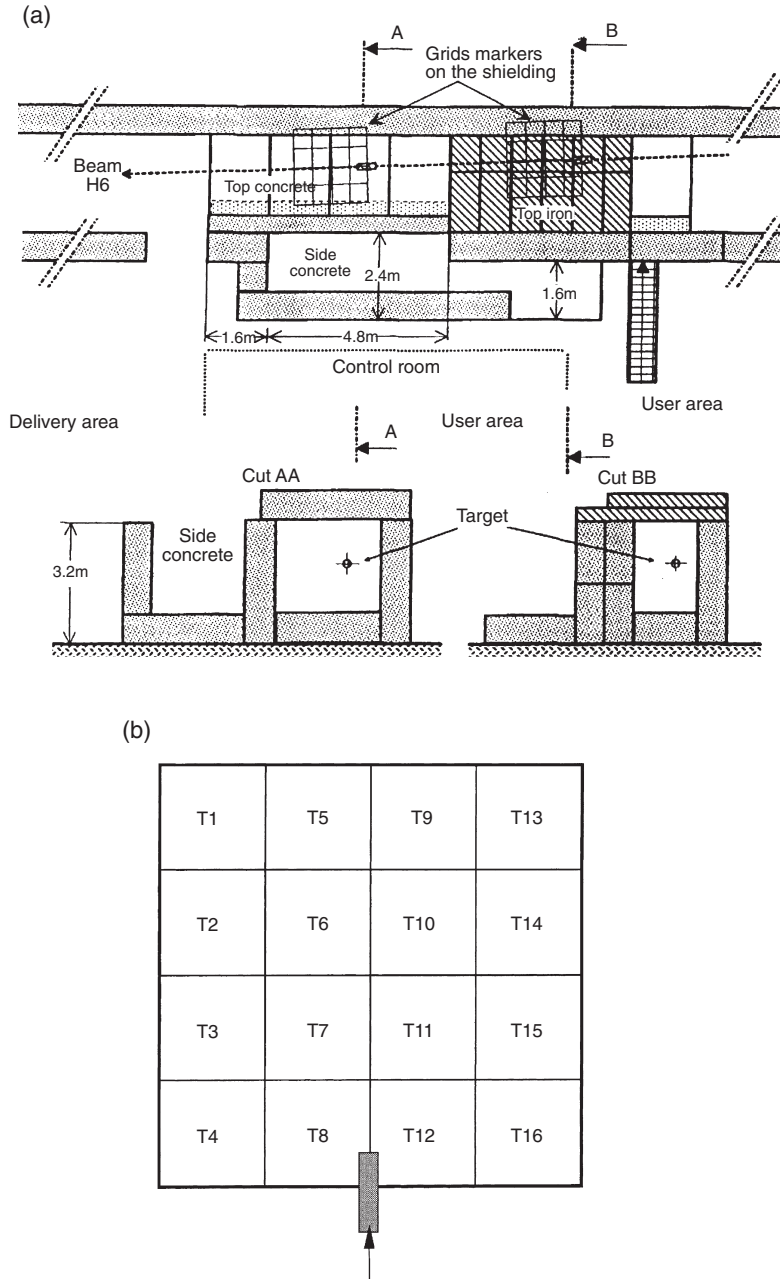

Figure 3. (a) Plan and sectional views of the CERF facility. (b) The reference grid with the 16 exposure locations used on the concrete and iron roof-shields.

by an air-filled precision ionisation chamber (PIC) at atmospheric pressure, placed in the beam just upstream of the copper target, connected to a current digitising circuit. One PIC-count corresponds (within $\pm 10\%$) to 2.2×10^4 particles impinging on the target. The proton beam is slow-extracted from the SPS over a few seconds (typically 2.6 s spill within an SPS cycle of 14.4 s, or 5.1 s spill every 16.8 s). During the spill the beam intensity is constant, thus producing a constant radiation field at the exposure locations. Typical values of dose equivalent rates are 1–2 nSv per PIC-count on top of the 40 cm iron roof-shield and about 0.3 nSv per PIC-count outside the 80 cm concrete shields (roof and side). By adjusting the beam intensity on the target one can vary the dose equivalent rate at the reference positions, typically in the range from $25 \mu\text{Sv}\cdot\text{h}^{-1}$ to $1 \text{mSv}\cdot\text{h}^{-1}$ on the iron roof-shield and from 5 to $600 \mu\text{Sv}\cdot\text{h}^{-1}$ on the 80 cm concrete roof or lateral shield. The energy distributions of the various particles (mainly neutrons, but also photons, electrons, muons, pions and protons) at the various exposure locations have been obtained by Monte Carlo simulations performed with the FLUKA code^(22–25). Details of the latest simulations are given elsewhere⁽²¹⁾. Here we shall just recall that the entire experimental area was accurately modelled using a combinatorial geometry. Calculations were performed for four cases, i.e. beam momentum of 120 GeV/c or 205 GeV/c and positive or negative particles. The 205 GeV/c and the negative 120 GeV/c beams were used in the past, whilst since 1996 all experiments are performed with a beam of 120 GeV/c positive particles. The neutron and photon energy distributions calculated for a primary beam of positive particles with 120 GeV/c momentum (35% protons, 61% pions and 4% kaons, as determined experimentally) are shown in Figures 4(a) and 4(b). It should be noted that these are absolute energy distributions per primary beam particle incident on the copper target, obtained by multiplying the FLUKA differential fluences (in particle/GeV/cm²/primary) by the width of the energy bin.

In general the neutron energy distributions do not change in shape from 120 GeV/c to 205 GeV/c, for either positive or negative particles, and only the absolute fluence per incident particle is larger for the higher energy. The spectrum outside the iron shield is dominated by neutrons in the 0.1–1 MeV range. The energy distribution outside the concrete shield shows an additional large relative contribution of 10–100 MeV neutrons. Therefore these exposure locations provide wide spectrum radiation fields well suited to test dosimetric instrumentation under different conditions. The latter, in particular, reproduces fairly closely, although not exactly, the neutron field produced by cosmic rays at commercial flight altitudes (Figure 4(c)). Since the CERF neutron field reproduces approximately the field at flight level, and because the shape of the neutron energy distribution in the atmosphere does not change much with altitude and latitude, the CERF spectrum is

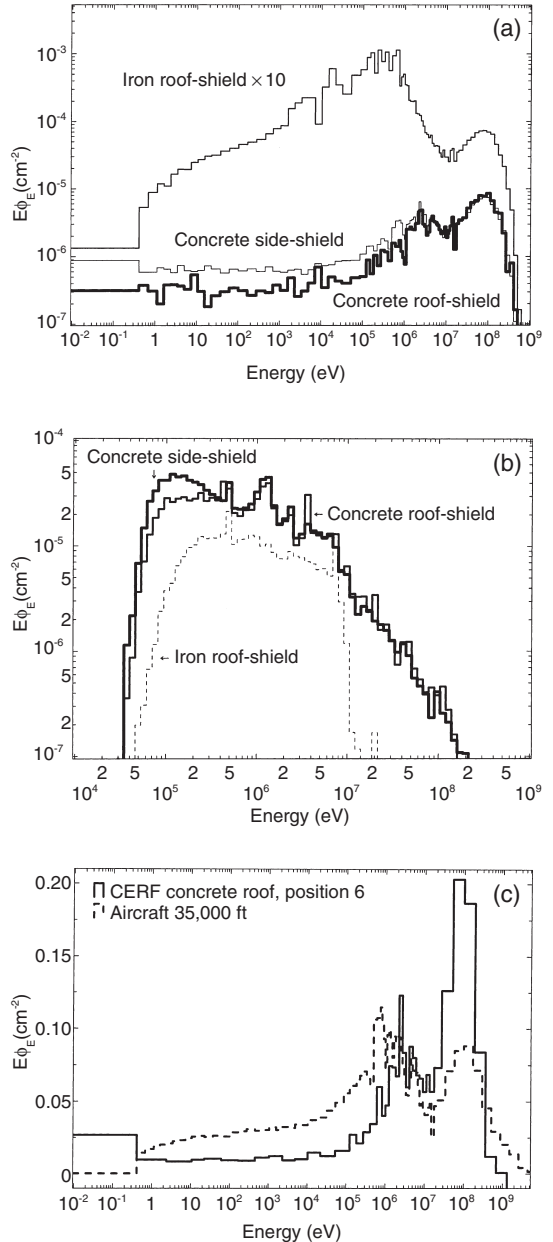

Figure 4. Neutron (a) and photon (b) spectral fluences on the concrete roof-shield, on the iron roof-shield and on the 80 cm thick concrete side-shield (neutrons or photons per primary beam particle incident on the copper target). (c) Comparison of the CERF neutron spectrum on the concrete roof-shield (position 6 on the grid of Figure 3(b)) with the neutron spectrum at an altitude of 10.6 km (35,000 feet) as calculated by Heinrich *et al.*⁽²⁶⁾. The total fluence is normalised to unity.

considered in most cases a sufficiently good representative of the neutron field at cruising altitude irrespective of route. A correction should usually be applied to take account of the difference in response of the device under test for the CERF spectrum relative to the neutron spectrum in the atmosphere, but this correction is not very sensitive to the sometimes large uncertainties in the high-energy neutron response data of the device (see, for example, Reference 27. The neutron spectrum behind the side 80 cm thick concrete shield is similar to the spectrum on the concrete roof-shield, but presents an increased low energy tail due to backscatter. On the other hand, it is much less affected by the muon background (see below). The fluence rate of other hadrons is much lower than that of neutrons. As seen from Figure 4(b), the photon fluence is almost one order of magnitude less than that of neutrons on the iron roof-shield, but almost a factor of two higher than the neutron fluence on the concrete roof-shield, because of the contribution from (n, γ) reactions. The electron fluence is about one order of magnitude less than that of neutrons and the muon fluence almost three orders of magnitude less. However, an additional muon component is also present, which comes directly from the upstream H6 beam line and adjacent lines, as well as from pion decay in the beam line. These muons stream over the concrete and iron roof-shields. Their intensity depends on various factors which are not under direct control, such as the intensity of secondary beams in neighbouring beam lines. This contribution is discussed in some more detail below.

The accuracy of the calculated neutron spectral fluences was verified in the past by extensive measurements made first with a BF₃ proportional counter enclosed in polyethylene cylinders of different thickness⁽²⁸⁾ and subsequently with a Bonner sphere spectrometer (BSS). Past measurements were done with a standard BSS⁽²¹⁾: a ³He proportional counter employed bare and within a set of five polyethylene spheres

(83 mm, 108 mm, 133 mm, 178 mm and 233 mm in diameter), with the addition of the spherical version of the LINUS rem counter as high-energy channel⁽²⁹⁻³²⁾. The excellent agreement found between the FLUKA predictions and the experimental results was confirmed by recent neutron spectrometry measurements performed with a BSS which now includes two dedicated high-energy channels based on the LINUS design^(33,34).

Of these two new channels, the first ('Ollio') is a sphere with a diameter of 255 mm and consists of moderator shells of (from the central ³He proportional counter outwards) 3 cm polyethylene, 1 mm cadmium, 1 cm lead and 7 cm polyethylene thickness. This configuration suppresses the response to incident neutrons with energies lower than 100 keV and increases it for energies above 10 MeV and up to 1 GeV, as compared to the 233 mm sphere of our conventional BSS. However the response function still shows the peak at about 10 MeV which is typical for all large detectors of a BSS. The second detector ('Stanlio'), with a diameter of 118.5 mm, consists of moderator shells of 2 cm polyethylene, 1 mm cadmium and 2 cm lead thickness. Its response function does not show the peak at 10 MeV, so that Stanlio is a useful complement to the other detectors. At low energies it behaves like a small Bonner sphere, but at high energies the response is increased compared to the 233 mm sphere. The measurements were performed with a 120 GeV/c positive hadron beam on the concrete roof-shield of CERF, exactly in the same position where the spectrum had been calculated with FLUKA, i.e. 25 cm above the concrete roof shielding on top of the copper target. The computed response functions of the extended BSS to monoenergetic neutrons were folded with the spectral fluences of Reference 21 (Figure 4(a)) and compared with the experimental count rates. These latest results are given in Table 1. The quoted uncertainties are only statistical and do not include systematic uncertainties in the FLUKA code.

Table 1. Experimental and calculated absolute response of the extended Bonner Sphere Spectrometer to the broad neutron spectrum on the concrete roof-shield of CERF, for a 120 GeV/c positive hadron beam (61% pions, 35% protons and 4% kaons) impinging on the copper target.

Sphere	Response (counts per incident hadron on the copper target)		
	Experimental	Calculated	Ratio (calc/exp)
81 mm + cadmium	$(1.53 \pm 0.08) \times 10^{-5}$	$(1.54 \pm 0.10) \times 10^{-5}$	1.01 ± 0.08
81 mm	$(2.24 \pm 0.10) \times 10^{-5}$	$(2.29 \pm 0.14) \times 10^{-5}$	1.02 ± 0.08
108 mm	$(3.02 \pm 0.13) \times 10^{-5}$	$(2.96 \pm 0.24) \times 10^{-5}$	0.98 ± 0.09
133 mm	$(3.55 \pm 0.17) \times 10^{-5}$	$(3.36 \pm 0.24) \times 10^{-5}$	0.95 ± 0.08
178 mm	$(3.59 \pm 0.17) \times 10^{-5}$	$(3.50 \pm 0.26) \times 10^{-5}$	0.97 ± 0.09
233 mm	$(3.12 \pm 0.15) \times 10^{-5}$	$(3.09 \pm 0.19) \times 10^{-5}$	0.99 ± 0.08
Stanlio	$(1.76 \pm 0.08) \times 10^{-5}$	$(1.88 \pm 0.20) \times 10^{-5}$	1.07 ± 0.12
Ollio	$(2.15 \pm 0.10) \times 10^{-5}$	$(2.61 \pm 0.15) \times 10^{-5}$	1.21 ± 0.09

The reference values of neutron ambient dose equivalent, $H^*(10)$, on the concrete and iron roof-shields are given in Table 2 for a 120 GeV/c positive beam. The values are obtained by folding the neutron spectral fluence calculated by FLUKA at the centre of each of the 16 squares of the grid, 25 cm above the shield (i.e. at the centre of a $50 \times 50 \times 50 \text{ cm}^3$ air volume) with the fluence-to-ambient dose equivalent conversions coefficients of ICRP 74 (up to 19 MeV)⁽³⁵⁾ and of Ferrari and Pelliccioni (above 19 MeV)⁽³⁶⁾. The values are mapped according to the grid shown in Figure 3(b). The statistical uncertainties of the Monte Carlo calculations are less than 2% for the concrete shield and less than 1% for the iron shield. The values are normalised to one unit of the beam monitor (PIC-count). The microdosimetric spectra measured on the concrete and iron roof-shields as well as on the 80 cm thick concrete side-shield by the HANDI TEPC are shown in Figure 5. The similarity of the absorbed dose distribution in lineal energy y on the concrete roof-shield and at flight altitude⁽³⁷⁾ is shown in Figure 6.

MUON BACKGROUND

At the measurement sites on the concrete and iron roof-shields there is a significant low-LET background radiation field. This background, which is timed to the pulsed structure of the beam, is not coming from interaction of the beam in the copper target but is mainly due to high-energy muons originating from pion decay in the beam line, with some contribution from hadron beam losses upstream in the H6 or neighbouring beam lines. If not taken into account, this background appears as an apparent non-linearity of a detector response when measurements are performed at different intensities of the incident hadron beam. This concerns ionisation chambers, TEPC and other active devices that have considerable sensitivity to low-LET radiation. On the other hand, there is no significant muon background at the side concrete shielded positions.

Various measurements^(38–41) have shown that, first,

the muons are also present with the H6 beam switched off. This means that the muon intensity is essentially independent of the intensity of the hadron beam on the copper target and thus cannot be normalised to the PIC-counts. Second, there is a strong gradient of the muon fluence when moving from the Salève to the Jura side of the facility (Figure 2), due to a large muon contribution from the neighbouring H8 beam line on the Salève side. Third, there is a small contribution of muons coming from the H6 beam line. This additional component is however not originating from the H6 production target, which is seen under a big angle, but rather from the upstream collimators that are used to limit the beam intensity and hence are a source of penetrating muons. For typical high intensity beam conditions, the muon background ranges from 3 to 12 pGy per PIC-count moving from the Salève side to the Jura side of the concrete roof-shield. This should be compared with a total dose equivalent on the concrete roof-shield of typically 300 to 400 pSv/PIC-count respectively, of which 50 to 75 pSv/PIC-count resulting from low-LET particles ($<6 \text{ keV} \cdot \mu\text{m}^{-1}$).

The muon background is obviously more important at low beam intensities⁽⁴⁰⁾. The ratio of low-LET to total dose equivalent increases from a few per cent for beam intensities above about 2000 PIC-counts per SPS pulse, to about 10% at 1000 PIC-counts per pulse and up to well above 50% for low beam intensity of a few hundreds PIC-counts per pulse.

Since the muon background is mostly independent of the intensity in the H6 beam line but changes with factors like beam composition (the pion fraction is a function of beam momentum) and intensity in the neighbouring beam lines, it is not exactly reproducible from run to run. The background must be checked before each experiment with low-LET sensitive devices. Nevertheless, the CERF mixed neutron, photon and muon field was used to test, before its use on board aircraft, a method of separating TEPC pulse heights for non-charged and charged particles using an active shielding detector developed by PTB⁽⁸⁾.

Table 2. Reference values of neutron ambient dose equivalent, $H^*(10)$, on the concrete and iron roof-shields, for a beam of positive particles with 120 GeV/c momentum (35% protons, 61% pions and 4% kaons) incident on the copper target, calculated by Monte Carlo. The values are mapped according to the grid shown in Figure 3(b). The statistical uncertainties are less than 2% for the calculations for the concrete shield and less than 1% for the iron shield. The $H^*(10)$ values are normalised to one unit of the beam monitor (PIC-count), with one PIC-count = 2.2×10^4 hadrons impinging on the target.

Neutron ambient dose equivalent, $H^*(10)$ (pSv per PIC-count)							
	Concrete roof-shield				Iron roof-shield		
216	254	253	207	1041	1286	1203	732
225	270	270	222	1170	1490	1454	1002
213	267	265	207	1238	1602	1596	1099
185	223	221	182	1137	1493	1471	1005

BEAM MONITORING

The intensity of the SPS secondary beam to CERF is monitored by a precision ionisation chamber (PIC) installed just upstream of the copper target. Both the calculated spectral fluences and the data of the experi-

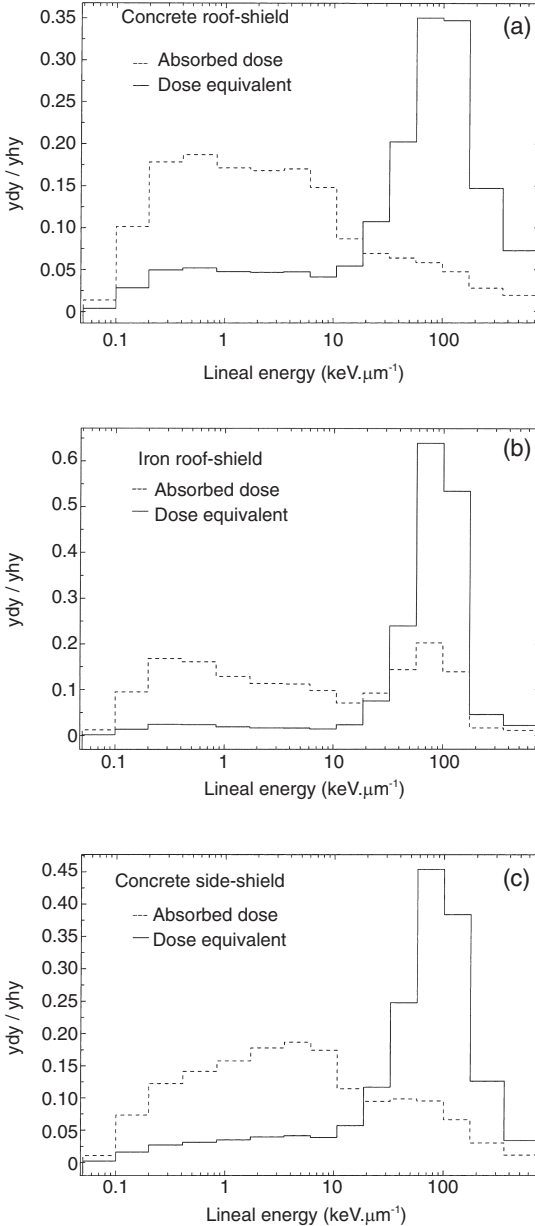

Figure 5. Distribution of absorbed dose, $d(y)$, and dose equivalent, $h(y)$, in lineal energy y , measured with the HANDI TEPC on the concrete roof-shield (a), on the iron roof-shield (b) and on the 80 cm thick concrete side-shield (c).

ments performed at CERF are usually normalised to the intensity of the beam impinging on the target. Therefore a good knowledge of the calibration factor of the PIC is essential.

In 1993/94 a series of in-beam activation measurements were made, to characterise the beam intensity and composition (the pion to proton ratio) of different beam momenta^(42–46). For this purpose three types of carbon activation detectors were used: small plastic scintillators, graphite discs and polyethylene foils of different thickness in order to study the effect of cascade build-up as well. The reactions used were $^{12}\text{C}(p,pn)^{11}\text{C}$ for protons and $^{12}\text{C}(\pi,\pi n)^{11}\text{C}$ for pions. Additional measurements with aluminium plates were performed looking at the ^{18}F and ^{24}Na activation. The induced activity of these detectors was measured with a 7.62 cm \times 7.62 cm (3" \times 3") NaI detector system by counting the 0.511 MeV gamma rays from positron annihilation. In addition the plastic scintillator was placed after exposure in the beam on top of a 12.7 cm (5") photomultiplier tube. The scintillator then detects its own positrons from the ^{11}C decay. All these measurements gave a calibration factor of 2.2×10^4 particles per PIC-count, with an uncertainty of $\pm 10\%$. This value was recently re-measured more precisely by comparing the response of the PIC with that of scintillators that are part of the beam line instrumentation^(47,48). These latest measurements gave a value of $(2.3 \pm 0.1) \times 10^4$ particles per PIC-count.

OVERVIEW OF EXPERIMENTAL APPLICATIONS

Several measurement campaigns have taken place at CERF starting in 1992. Many institutions from all over Europe, as well as from the USA, Canada and Japan, have used the facility to test various types of passive and active detectors. As mentioned above, all instruments and dosimeters used for on-board measurements in the framework of the EU funded programmes have

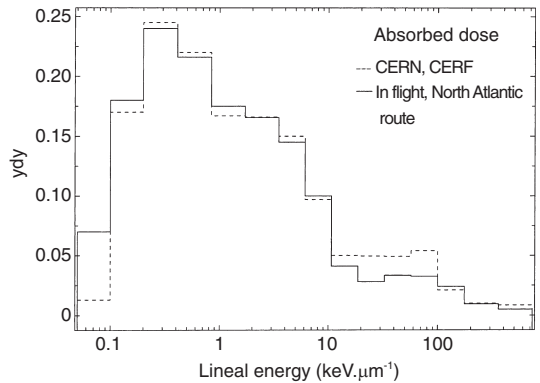

Figure 6. Distribution of absorbed dose, $d(y)$, in lineal energy y , on the concrete roof-shield of CERF and at flight altitude on a north Atlantic route⁽³⁷⁾, normalised to the same total dose.

been periodically tested and calibrated at CERF⁽³⁾. In addition, several other institutions have performed various types of measurements at the facility over the years. To show the range of applications of CERF, this section gives a (possibly non-exhaustive) overview of the most important dosimetric applications for which the facility has been used. This overview groups, somehow arbitrarily, the investigations in the following categories: test and intercomparison of either active instrumentation or passive devices, active and passive dosimeters used for individual monitoring, in-flight measurements based on CERF calibration either on commercial flights or in space, and radiobiological studies. A few representative experimental results, some previously unpublished, are given.

Active instrumentation

A first intercomparison of the response of dosimeters used in high-energy stray radiation fields was carried out in 1992 at the 'pre-CERF' facility. At that time the facility had not yet the present configuration. The beam used was 200 GeV/c positive hadrons (2/3 protons and 1/3 positive pions) and the target assembly consisted of an iron block 140 cm long, 50 cm wide and 30 cm high. Top shielding, where measurements were performed, was either 80 cm thick concrete or 60 cm thick iron. Measurements were also made in front of the access door to check the dosimeter response in a softer field. The instruments tested were different TEPCs, conventional and extended range rem counters, a recombination chamber type REM-2⁽⁴¹⁾ (a cylindrical, parallel-plate ionisation chamber with 25 tissue-equivalent electrodes, manufactured in Poland. It has a volume of 2000 cm³, mass of 6 kg and an effective wall thickness of 2 g.cm⁻²; it is filled with a mixture of methane and nitrogen (5%) at a pressure of about 1 MPa), the CERBERUS (a multiple-detector system, developed at CERN, consisting of a rem ionisation chamber, a tissue-equivalent ionisation chamber, an air-filled aluminium chamber and a ¹¹C activation detector), a set of Bonner spheres and NTA films⁽⁴⁹⁾.

Golnik and co-workers have investigated the application of recombination chambers in the determination of microdosimetric data, based on the comparison of saturation curves measured for mixed radiation with those for reference gamma radiation (¹³⁷Cs). Measurements performed in the CERF field showed that the low-LET component predominates in the absorbed dose, on both the concrete and iron roof-shields and equals 90% for the former and 73% for the latter. These values are in good agreement with the results of measurements with the HANDI TEPC in use at CERN⁽⁵⁰⁾. The values of ambient dose equivalent rate obtained by different types of recombination chambers compared well with those from other devices⁽⁵¹⁾. In particular, a REM-2 recombination chamber was used to investigate the low-LET background radiation⁽⁴¹⁾.

The responses of various types of rem counters were compared on the concrete roof-shield in a dedicated experiment. Two of the instruments were of conventional design and four were cylindrical or spherical versions of the LINUS. The results, given in Table 3 together with values measured by the CERN HANDI TEPC, showed a good agreement amongst the various LINUS. The two conventional rem counters underestimated the total dose equivalent by about 40%, due to their reduced response above 20 MeV. This result was found in perfect agreement with previous measurements with high energy neutrons^(30-32,52). The value of ambient dose equivalent for the several LINUS was also found in remarkable agreement with that measured by the TEPC⁽⁵³⁾.

Lindborg and co-workers have developed the 'Sievert-instrument', a device consisting of two TEPCs with diameter of 11.5 cm simulating mean chord lengths of 2 μm, and electronics units for analysing the signal according to the variance-covariance method. The instrument is calibrated in H*(10) in a ¹³⁷Cs field and its response to broad neutron fields was investigated at the CERF facility. With the assumption that the LET distribution in the atmosphere is reasonably well characterised by a combination of a CERF field and a low-LET field, the instruments can be used directly for measurements on board⁽⁵⁴⁻⁵⁶⁾.

First measurements of the response of high-sensitivity MOSFET devices to a simulated cosmic neutron field were performed at CERF by Benson *et al*⁽⁵⁷⁾. A total of 18 devices of different design were tested, some having the surface of the silicon wafer covered with layers of polyethylene of different thicknesses to promote (n,p) reactions with high energy neutrons and thus enhance the response of the detector to the neutron component of the radiation field. This preliminary investigation has shown that, in their present form, these devices are too insensitive for cosmic neutron dosimetry. Alternative methods to increase their sensitivity need be investigated.

Passive dosimetry

At CERF Spurny and Bottolier-Depois have investigated three microdosimetry methods based on a TEPC, on chemically etched polyallyldiglycolcarbonate (PADC) solid state nuclear track detectors and on bubble detectors. A LET spectrometer has been developed based on PADC. The microdosimetric spectra determined on board aircraft and behind the shielding of high-energy particle accelerators were compared. The spectra obtained with the NAUSICAA TEPC and with the PADC LET spectrometer agree well; their form is similar in the CERF reference field and on board aircraft. Bubble detectors were tested at CERF and on board aircraft, to verify their relative response with different thresholds in different radiation fields⁽⁵⁸⁾.

The extension of the response of bubble detectors to

high-energy neutrons was experimentally determined at CERF by exposing the dosimeters inside lead converters of various thicknesses. Monte Carlo calculations were performed to assess the effect of the lead converter on the neutron spectral fluence. The experimental results were compared with the calculated ambient dose equivalent obtained by folding the response of the detectors with the modified neutron spectrum. Both the experimental and the Monte Carlo results indicated that the dosimeter can be made to respond correctly to neutron energies above 20 MeV; the required lead thickness is 1 cm to 1.5 cm. It has also been shown that this additional material does not perturb the detector response to lower energy neutrons⁽⁵⁹⁾.

CR-39 nuclear track detectors have been employed on a number of subsonic and supersonic aircraft to measure charge spectra and LET spectra at cruising altitudes. In order to test the overall validity of the technique, measurements were carried out at the CERF facility and good agreement was found with dose values obtained using mainly heavy ion calibration⁽⁶⁰⁾.

Individual monitoring

Spurny has tested several individual dosimeters for both the low-LET and high-LET components in high-energy radiation reference fields at JINR (Dubna, Russia) and at CERF as well as on board aircraft during commercial flights. Three types of electronic personal dosimeters based either on Si diodes or on a small GM counter and several passive dosimeters (TLDs, Al-P glass and photographic films) were used for the low-

LET component. For the high-LET component, nuclear emulsions, albedo dosimeters, etched track detectors in contact with fissile radiators, PADC etched track detectors and two types of bubble detectors were investigated⁽⁶¹⁾. The relative response of the high-LET dosimeters to a TEPC is shown in Table 4. The response of Czech routine personal dosimeters in high-energy radiation reference fields was also investigated at JINR and at CERF. The study has demonstrated that the values obtained through the routine interpretation procedure never lead to an underestimation of exposure but rather to a large (up to a factor of 5) overestimation. If information on the neutron spectrum is available for the interpretation of the dosimeter reading, the agreement of values obtained by means of the routine neutron dosimeter and reference values becomes quite satisfactory⁽⁶²⁾.

An intercomparison of personal dosimeters from seven US accelerator facilities (ANL, BNL, LBNL, LANL, PNNL, SLAC and TJNAF) was conducted at CERF. Part of the dosimeters shipped to CERN were exposed at CERF, part to neutrons from a ²³⁸Pu-Be(α ,n) source and part were used as controls to correct for background radiation encountered during transit to and from CERN. The following types of dosimeters were investigated: Panasonic model 810 (⁶Li₂¹⁰B₄O₇ and ⁷Li₂¹¹B₄O₇) plus CR-39; Harshaw model 8816 neutron TLD (TLD-700 plus TLD-600)/etched track detectors; Harshaw model 8825 beta-gamma TLD-700; Harshaw model 8814 TLD (⁷LiF:Mg,Ti and ⁶LiF:Mg,Ti) plus CR-39 etched track detector; CR-39 etched track detectors in various forms and submitted to different etching

Table 3. Comparison of the response of rem counters in position 6 of the concrete roof-shield of CERF. The reference values measured by the CERN HANDI TEPC spectrometer are also given. The given uncertainty includes the statistical uncertainty on detector counts and the 10% uncertainty on the PIC-counts.

Detector	Calibration		Ambient dose equivalent (nSv/PIC)
	Factor (nSv/cts)	Procedure	
Studsvik (CERN)	0.98	H*(10), PuBe source	0.145 ± 0.016
Berthold (CERN)	0.353	H*(10), PuBe source	0.148 ± 0.015
Cylindrical LINUS (CERN)	1.49	H*(10), PuBe source	0.262 ± 0.029
Spherical LINUS (CERN)	0.92	H*(10), PuBe source	0.243 ± 0.028
Spherical LINUS (Univ. Mi)	0.776	H*(10), AmBe source	0.228 ± 0.025
Cylindrical LINUS (NRPB)	1.11	H*(10), AmBe source	0.247 ± 0.025

procedures; Panasonic model UD-802 using lithium tetraborate (LiBO_4) or $\text{Li}_2\text{B}_4\text{O}_7$:Cu and calcium sulphate (CaSO_4) or CaSO_4 :Tm. The experiment showed that if a field-specific calibration factor is used to correct the dose equivalent responses, the agreement with the reference dose equivalent is in the range 25 to 65% depending on dosimeter type⁽⁶³⁾.

A Japanese group has developed a real-time neutron personal dosimeter, which contains a fast and a slow neutron sensor. Both sensors are p-type silicon semiconductor detectors, the latter with a natural boron layer deposited around an aluminium electrode to detect α and Li ions from the $^{10}\text{B}(n,\alpha)$ reaction. A thin polyethylene radiator is in contact with the front surface of each sensor to produce recoil protons. Field measurements of the performance of the device were carried out around several nuclear facilities (reactors, accelerators and nuclear fuel handling facilities) including CERF (both on the concrete and iron roof-shields). The results showed that the dosimeter is able to provide a reading of the neutron dose equivalent within a factor of 2 of the real value. The device also proved insensitive to gamma rays up to dose rate of 1 Sv.h^{-1} . The dosimeter is now commercially available from Fuji Electric Co. Ltd⁽⁶⁴⁾.

In-flight measurements based on CERF calibration

Measurements were performed on Concorde using the NRPB (UK) passive survey meter, which uses 30 to 40 dosimeters for both the neutron and non-neutron component of the field. The survey meter uses dosimeters from the NRPB routine personal dosimetry services (TLDs for the non-neutron component and PADC etched track detectors for the neutron component). A calibration factor was determined for the neutron fluence response of the passive survey meter for the CERF concrete roof-shield. Both batch and sheet dependence of this calibration factor have been investigated. It was

concluded that a sheet and batch calibration factor can be applied, but a periodic check should be made. The results are given in Figure 7. It is assumed that the fluence response measured for the CERF spectrum can be corrected by the ratio of the predicted responses of the passive survey meter for the calculated neutron spectrum in the atmosphere by Heinrich *et al*⁽²⁶⁾ to that calculated for CERF. For the PADC etched track detectors, the use of the CERF calibration is considered to give a good estimate, within 20 or 30% systematic uncertainty, of effective dose or ambient dose equivalent for the neutron component of the cosmic radiation field in aircraft⁽¹²⁾.

As part of a continuing assessment of the cosmic radiation exposure of Canadian based aircrew, a TEPC was used to take dosimetric measurements on board 64

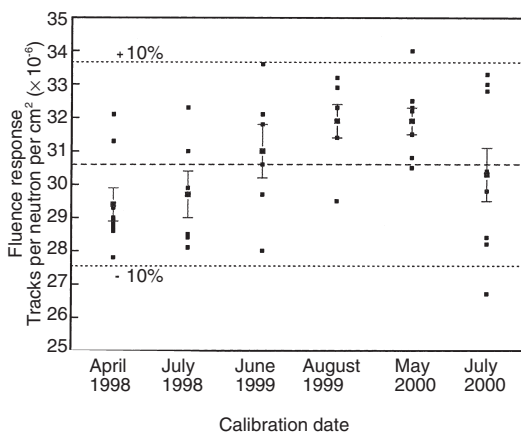

Figure 7. Calibration measurements of the NRPB passive survey meter, PADC neutron detectors at CERF (April 1998 to July 2000)⁽¹²⁾. Small symbols, individual sheet results. Large symbol, mean for that measurement \pm SEM. (---) overall mean = 30.6 ± 0.3 (SEM).

Table 4. Response of individual dosimeters to the high-LET component of CERF⁽⁶¹⁾ relative to a TEPC.

Dosimeter	Relative response of dosimeter to TEPC	
	Concrete roof-shield	Iron roof-shield
^6LiF in albedo PGP DIN	0.10 ± 0.02	0.40 ± 0.09
Nuclear emulsion NTA	3.70 ± 0.90	1.50 ± 0.30
Etched track detector with fissile radiators	2.90 ± 0.50	1.60 ± 0.20
PADC	0.35 ± 0.06	0.26 ± 0.04
Etched track detector		
BDND BD 100R	0.57 ± 0.09	1.35 ± 0.18
BDND PND	0.63 ± 0.11	1.49 ± 0.21
SDD 100	0.59 ± 0.11	0.66 ± 0.09
SDD 1000	0.77 ± 0.15	0.27 ± 0.06
SDD 6000	1.14 ± 0.20	0.24 ± 0.05

flights from September 1998 to October 1999. In conjunction with the in-flight measurements, the operation of the TEPC was verified using several common radioisotopic sources and in the CERF neutron field. The values of various microdosimetric quantities obtained from several terrestrial sources, including those obtained from the CERF spectrum, provided a useful comparison to the values obtained from the radiation field at jet altitudes⁽⁶⁵⁾.

A diverse array of both passive and active instruments, to cover all radiation components of the field at aviation altitudes, was employed in the Italian national survey of aircrew exposure⁽¹⁰⁾. The detectors used were the LINUS; the ANPA stack, a passive multidetector stack including bubble detectors (for low-energy neutrons), bismuth-fission track detectors (for high-energy neutrons), cellulose nitrate (LR-115 from Kodak) and polycarbonate track detectors for high-Z particles, and various TLDs (including the hypersensitive Chinese lithium fluoride GR-200) for the low-LET component; the DIAS stack consisting of 20 sheets of CR-39 used to determine the fluence and type of charged particles as well as their LET; TEPC; PADC (CR-39); a high-pressure ionisation chamber Reuter-Stokes type RSS-112 (based on a spherical stainless steel ionisation chamber filled with ultra-pure argon gas under high pressure). All these dosimetric systems have provided consistent results when exposed together at CERF⁽⁶⁶⁾. An example of the agreement obtained between the range of instruments employed is shown in Table 5⁽¹⁵⁾.

Measurements related to space programmes

CERF has also been used to test instrumentation flown in space. The response of a space shuttle TEPC was investigated at the facility and compared to other dosimetric devices⁽⁶⁷⁾. When exposed to high-energy neutrons, the dose equivalent response was found nearly the same as that of the HANDI TEPC of CERN. Over the LET range produced primarily by charged particles ($<20 \text{ keV} \cdot \mu\text{m}^{-1}$) the response of the TEPC is nearly identical to that of the DOSTEL telescope, consisting of two 300 μm thick Si detectors, developed at the University of Kiel⁽⁶⁸⁾.

Table 5. Measured and calculated ambient dose equivalent rates at CERF relative to the CERN HANDI TEPC (high-LET component $>6 \text{ keV} \cdot \mu\text{m}^{-1}$)⁽¹⁵⁾.

FLUKA calculated/CERN TEPC	$0.91 \pm 0.07^*$
USAAR HANDI/CERN TEPC	0.88 and 1.02
ANPA stack/CERN TEPC	0.95 ± 0.1
NRPB etched track detectors (predicted)/CERN TEPC	1.2 ± 0.1
DIAS etched track detectors/CERN TEPC	1.18 ± 0.12

*Average over all 16 concrete roof-shield locations

A new active personal neutron dosimeter developed at PTB for use in the space station MIR and the space shuttle, based on silicon diodes, shows improved sensitivity to neutrons, rejects charged particles by anticoincidence and, in addition, gives information on the neutron spectrum. It consists of a stack of silicon detectors sandwiched between layers acting as neutron converters, moderators and absorbers. A response matrix has been determined by measurements in monoenergetic neutron reference fields. The first results of measurements at CERF showed good agreement with energy distributions calculated by the FLUKA code⁽⁶⁹⁾. The above active device was further developed for measuring the energy and directional distribution of neutron fluence in fields of broad energy spectra and with a high background of photon and muon radiation. Six detector capsules were mounted on a 30 cm diameter polyethylene sphere, each of them containing four silicon detectors with different converters and shields. The energy and directional distribution of the fluence is reconstructed from the pulse height spectra and from the response function determined with monoenergetic neutron fields. The dose equivalent measured with the spectrometer agrees within 25% of the reference value. The results show that this directional spectrometer provides reasonable results in fields with wide energy distributions, even in the case of intense low-LET background as in CERF^(70,71).

Other applications

A radiobiological investigation was also conducted at CERF, in spite of the lack of supporting structure at CERN for this type of application. Heimers has determined the RBE of a mixed neutron-gamma simulated cosmic radiation field and its high-LET component, on the induction of chromosome aberrations in human lymphocytes. The results of this preliminary investigation showed a high RBE of cosmic radiation and its neutron component in comparison with ^{60}Co gamma radiation — up to 64, and up to 113 when calculating only the high-LET component⁽⁷²⁾. As these results raised some debate, there are plans to repeat the experiment in the course of one of the CERF runs of 2002.

Other experimental results obtained at CERF in the field of neutron spectrometry and dosimetry are reported in the literature^(73–80). It is also worth mentioning that, although most of the beam time was dedicated to test dosimetric instrumentation, the facility has also been exploited for other uses, such as verifying the effect of radiation on computer memories⁽⁸¹⁾, testing prototypes of a beam loss monitor for the future CERN Large Hadron Collider (LHC)⁽⁸²⁾ and testing detector components for the upcoming LHC experiments⁽⁸³⁾.

LATEST DEVELOPMENTS

In a space station in low-earth orbit neutrons make

an important contribution to the personal dose equivalent⁽⁸⁴⁾. Most of the neutrons inside the station result from nuclear interactions of the charged particles (mainly galactic protons and protons trapped by the earth's magnetic field) with the wall of the vessel. A plot of $E\Phi_E$ against $\log(E)$, where Φ_E is the neutron fluence, shows peak intensities at about 1 MeV and 100 MeV, while for protons the peaks show at about 100 MeV (trapped proton source) and in the GeV region (galactic proton source). In fact, as mentioned in the previous section, for the evaluation of dosimeters used in space the calibration value determined at CERF was

taken for fast neutrons because this field is considered to be most similar to that in space.

Nevertheless, several other particles contribute to the dose in a space station or in a shuttle orbiting around the earth, or in a spacecraft travelling, for example, to Mars. Also, astronauts performing extravehicular activities are directly exposed to the cosmic ray field. It was thus decided to study whether a different shielding configuration at CERF could produce a more complex radiation field, rich in high-energy particles, which could be of interest for forthcoming measurements in the framework of the space programme. To investigate

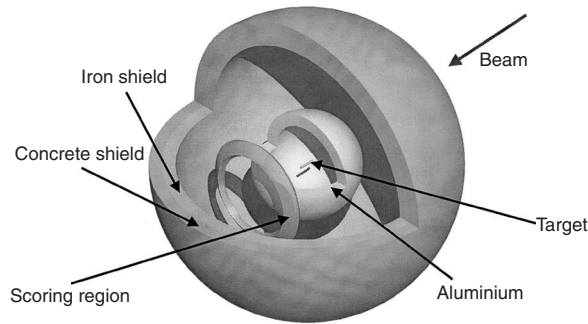

Figure 8. Simplified spherical geometry used in the preliminary calculations for the upgrade of the CERF facility to reproduce the radiation field in a space vessel.

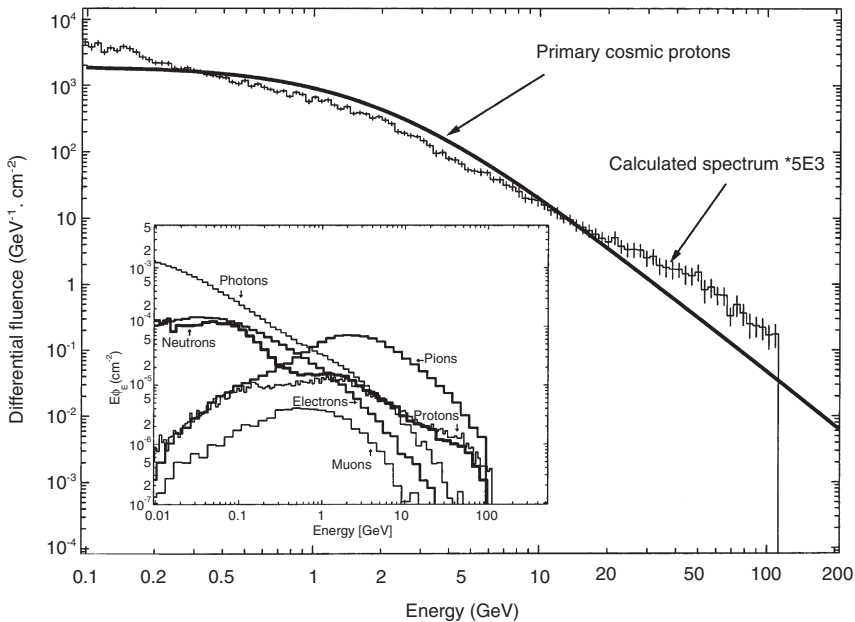

Figure 9. Particle spectral fluences in the 0° – 10° angular region for a positive 120 GeV/c beam (particles per primary beam particle incident on the target). The target is copper, 50 cm thick and 7 cm in diameter; 10 cm thick aluminium shield placed at 1 m from the target; external shielding is 40 cm iron backed by 40 cm concrete placed at 2.5 m distance from the aluminium slab.

this possibility, preliminary Monte Carlo simulations were performed with the FLUKA code^(22–25) in a simplified spherical geometry (Figure 8). The aim was to understand if a given target/shielding combination and angular scoring region would indicate a promising situation which could subsequently be investigated more thoroughly by modelling the complete facility. Calculations were performed for the ‘standard’ 50 cm thick, 7 cm diameter copper target as well as for smaller targets. The study aimed at producing a radiation field mainly rich in high-energy protons similar to that found in the stratosphere⁽⁸⁵⁾ or high-energy neutrons and other secondary particles as found inside the space station or a spacecraft⁽⁸⁶⁾.

The target was at the centre of a spherical shield, with scoring done in conical regions 10° wide (0° to 90°). Neutrons, protons, pions, muons, photons and electrons were scored. A 10 cm thick aluminium shield was placed at 1 m distance from the target. An additional layer of material acting as back shield (40 cm iron backed by 40 cm concrete) was placed at 2.5 m distance from the aluminium. The particle spectra in the forward direction (0° to 10° angular region) are shown in Figure 9. One should note, in particular, that the high-energy component (above 100 MeV) of the proton spectrum is similar to the energy spectrum of cosmic ray protons⁽⁸⁷⁾. Also, the neutron energy distribution extends up to about 100 GeV rather than the few hundreds MeV of the present CERF configuration on the concrete roof-shield. The simulations showed that the pion component decreases with respect to neutrons with increasing aluminium thickness and increasing emission angle.

The influence of primary beam momentum on the secondary particles produced was investigated in the range 40–400 GeV/c. The simulations have shown that the spectral shape and the secondary particle composition do not change much with beam momentum, and

only the absolute fluence per beam particle on target increases with increasing momentum. With increasing emission angle the neutron component becomes more and more dominant over the other particles.

CONCLUSIONS

The calibration of instruments and dosimeters at CERF is expected to continue to play an important role in the fourth EU funded programme on the investigation of radiation fields and dosimetry at aviation altitudes. There is also increasing interest by many research institutions outside the EU collaboration in using the facility, including measurements in the framework of the space programme. Promising Monte Carlo results have been obtained in view of extending the range of particle spectra provided at CERF. These preliminary results will have to be confirmed by more accurate calculations.

ACKNOWLEDGEMENTS

The operation of CERF is partially supported by the European Commission, Directorate General XII, contracts no. F13P-CT92-0026 (1992–1995), F14P-CT95-0011 (1996–1999) and FIGM-CT-2000-00068 (the present contract). A Fassò, M. Höfert, T. Otto, G. R. Stevenson and L. Ulrici have contributed substantially to the set-up, start-up and operation of the facility over recent years. Early Monte Carlo calculations were performed by G. R. Stevenson, the most recent ones by A. Ferrari, E. Nava and T. Rancati. In particular the authors wish to thank A. Ferrari for many useful discussions and T. Rancati for providing the data of Table 2. Figure 1 was taken from Reference 3, for which the authors wish to thank H. Schraube and D. O’Sullivan. They also wish to thank D. Bartlett for providing them with the latest results of the NRPC PADC calibration appearing in Figure 7.
